

A multiscale decomposition method for the optimal planning and scheduling of multisite continuous multiproduct plants

Sebastian Terrazas-Moreno, Ignacio E. Grossmann*

Department of Chemical Engineering, Carnegie Mellon University, 5000 Forbes Ave. Pittsburgh PA 15232, USA, grossmann@cmu.edu

Abstract

This paper addresses the solution of simultaneous scheduling and planning problems in a production-distribution network of continuous multiproduct plants that involves different temporal and spatial scales. Production planning results in medium and long-term decisions, whereas production scheduling determines the timing and sequence of operations in the short-term. The production-distribution network is made up of several production sites distributing to different markets. The planning and scheduling model has to include spatial scales that go from a single production unit within a site, to a geographically distributed network. We propose to use two decomposition methods to solve this type of problems. One method corresponds to the extension of bi-level decomposition of Erdirik-Dogan and Grossmann (2008) to a multi-site, multi-market network. A second method is a novel hybrid decomposition method that combines bi-level and spatial Lagrangean decomposition methods. We present four case studies to observe the performance of the full space planning and scheduling model, the bi-level decomposition, and the bi-level Lagrangean method, in profit maximization problems. Numerical results indicate that in large-scale problems, decomposition methods outperform the full space solution, and that as problem size grows the hybrid decomposition method becomes faster than the bi-level decomposition alone.

Introduction

The process systems engineering (PSE) community has been concerned with the integration of planning and scheduling in the process industry for the last two decades. One of the first examples is the work by Birewar and Grossmann (1990)

where aggregate sequencing constraints were included as part of the production planning problem of a multiproduct flow shop batch plant. A later review by Grossmann et al. (2002) established the need for discrete optimization models for solving the integrated planning and scheduling problem. Since then, a considerable number of papers have appeared on the subject of integration of planning and scheduling. The works by Hooker (2005), Stefansson and Shah (2006), Sung and Maravelias (2007), Erdirik-Dogan and Grossmann (2006,2008), Verderame and Floudas (2008), and Li and Ierapetritou (2009, 2010), are but a few recent examples. The review paper by Maravelias and Sung (2009) offers a more extensive description of recent developments.

The main argument for integration of planning and scheduling is that it is required for ensuring the feasibility of the scheduling decisions at the planning level and for improving the enterprise-wide operational and economic objectives (Grossmann, 2005). The single most important challenge is the computational intractability of optimization models dealing with simultaneous planning and scheduling. This is a result of integrating a medium or long term planning problem dealing with months and years with short term scheduling dealing with days or hours. In the case of a geographically distributed network (as in the case of a multi-site process network distributing to several markets), the problem involves not only different temporal scales, but also a range of spatial scales that go from single units in one plant to a multi-site distribution network.

Maravelias and Sung (2009) classify works in planning and scheduling in terms of the characteristics of the planning model and in terms of the solution method. The modeling approach can involve a detailed scheduling formulation extended to cover the planning horizon, aggregate or relaxed scheduling constraints, offline-surrogate formulations, or hybrid methods for rolling horizon. In terms of solution approach they can be hierarchical, iterative, or full-space. This paper proposes and algorithm for solving a multi-site planning and scheduling problem for continuous multiproduct plants in which we use an existing aggregate model for the planning problem (Erdirik-Dogan and Grossmann, 2008) of a single site, but extends it to multi-site setting (Jackson and Grossmann, 2003). The solution strategy uses an

iterative bi-level decomposition for dealing with the different temporal scales that result from the planning and scheduling integration, combined with Lagrangean decomposition (Guignard and Kim, 1987) to address the integration of spatial scales. The scheduling model embedded within the integrated planning and scheduling problem corresponds to a continuous time, slot-based model for a single-stage multi-product continuous plant with parallel lines and sequence dependent changeovers (Erdirik-Dogan and Grossmann, 2008).

Li and Ierapetrirou (2009, 2010) developed solution methods based on Augmented Lagrangean Relaxation (ALR) for planning and scheduling of batch processes where the objective is cost minimization. They exploit the bi-level structure of the problem and decompose it into scheduling sub problems for every time period and production site. Our work also uses a bi-level representation of the problem with an upper planning level and a lower scheduling level. However, we use a planning model with aggregated sequencing constraints in the upper level as opposed to a surrogate model with implicit objective function as they do. The solution method is also different since we decompose the upper-level planning problem into single-site and single-market problems to derive a relaxation bound for the integrated problem, while they decompose the lower level scheduling problem and enforce a penalty term through ALR in order to obtain a feasible solution of the original formulation.

In the next sections we define the integrated multi-site multi-market planning and scheduling problem for continuous multiproduct plants followed by the corresponding mathematical model. We then present a new hybrid algorithm for obtaining optimal or near optimal solutions of the simultaneous planning and scheduling problem. In a later section, several case studies of different sizes are solved using the proposed method. The paper concludes with some remarks and discussion of the numerical results.

Problem Statement

We model the market-facing end of the chemical supply chain as a process network where the objective is profit maximization from product revenues. As

seen in Figure 1, nodes in this network are either production sites or markets. Arcs in the network correspond to potential transportation links for shipping the products in the network. Each production node corresponds to a single stage continuous manufacturing facility that can produce several products, giving rise to a scheduling problem within each production node. The flow of products in the network is limited by the capacity of the production nodes, the shipping capacity of the arcs, and the demand in the market nodes. Production changeovers have a significant duration that is sequence-dependent. Therefore, scheduling decisions affect the extent to which it is possible to exploit the capacity of each production node.

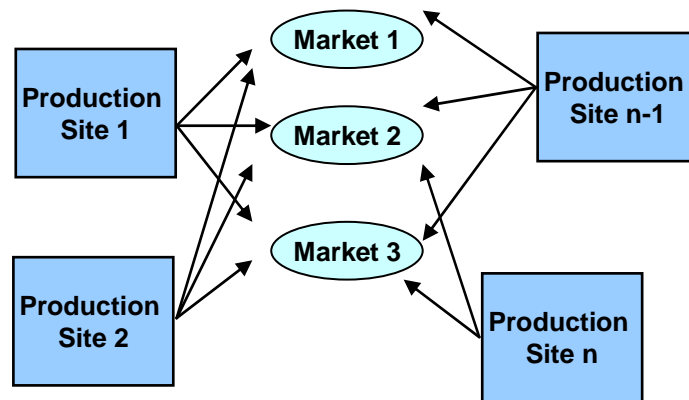

Figure 1. Production and distribution network

The description of the model of the chemical supply chain involves two different time scales. The long term time scale involves decision such as the amount of product manufactured in the production nodes and the flows of those products to the markets. The short term time scale involves scheduling and sequencing decisions in each production site. The objective is to maximize profit over a medium to long term planning horizon (weeks to months), while operating the network in the short-term (daily or hourly) so as to meet the product demands. In addition to the medium and long-term decisions for the planning problem and the short-term decisions for the scheduling at each production site, spatial scales due to the geographical distribution of the sites have to be integrated to achieve the optimum of the overall system. This integrated optimization problem is then as follows:

Given are:

- A set of products
- A set of production sites
- A set of single stage multiproduct continuous plants with parallel production lines
- A set of markets for the products
- A set of time periods for production planning
- The forecasted demand and price for each product at the end of the time periods
- The production cost and inventory holding cost for each product
- The changeover cost and time for each pair of products in each site
- The shipment cost for each product between each site and each market
- Production, storage, and shipment maximum capacities

The problem is to *determine*:

- Planning decisions for each time period
 - Amounts to be produced of each product at each site
 - Amounts to be stored in inventory at each site
 - Shipments between each production site and each market
- The production schedule at each site
 - Assignment of products and sequence in each production line at each time period
 - Start and end time for the production runs at each time period
 - Amount of product manufactured at each production run

with the *objective* of maximizing the profit, calculated as:

Sales – Production cost – Manufacturing cost – Changeover cost - Shipment cost

Mathematical Model

The models in the following section are an extension of the MILP model by Erdirik-Dogan and Grossmann (2008) for continuous multi-product plants with parallel lines in which time slots are postulated for the potential production runs.

Nomenclature

Index/Set

$i, k / I$	<i>indices/set of products</i>
ℓ / L	<i>index/set of time slots</i>
s / S	<i>index/set of manufacturing sites</i>
t / T	<i>index/set of time periods</i>
m / M	<i>index/set of markets</i>
n / N	<i>set of parallel lines</i>

Parameters

$\beta_t^{i,m}$	<i>Sale price of product i in market m during time period t</i>
$\alpha_s^{i,n}$	<i>Operating cost of product i in line n of production site s during time period t</i>
δ_s^i	<i>Inventory cost of product i in production site s during time period t</i>
$\gamma_s^{i,m}$	<i>Shipment cost between production site s and market m</i>
$TC_s^{i,k}$	<i>Cost incurred during a transition from product i to product k</i>
$a_s^{i,n}$	<i>Production rate of product i in in line n of production site s during time period t</i>
$bt_{t,s}^{i,k}$	<i>Transition time from product i to product k</i>
$x_{s,i}^{UB}$	<i>Upper bound on production of product i in production site s</i>
$v_{s,i}^{UP}$	<i>Maximum storage capacity for product i in production site s</i>
$f_{s,i}^{UP}$	<i>Maximum shipping amount between production site s and market m</i>
$d_t^{i,m}$	<i>Demand for product i in market m during time period t</i>
H_t	<i>Length of time period t</i>

mds_m^i Minimum percentage of demand of product i that has to be satisfied in market m

Variables

$x_{t,s}^{i,n,\ell}$ Production of product i in site s , slot ℓ , of line n in time period t

$x_{t,s}^{i,n}$ Production variable upper level problem

$p_{t,s}^i$ Aggregated production of product i of all lines in site s during period t

$v_{t,s}^i$ Inventory of product i in site s at the end of time period t

$vt_{t,s}^i$ Inventory variable for upper level problem

$\theta_{t,s}^{i,n,\ell} \theta_{t,s}^{i,n,l}$ Production time i in slot ℓ during period t in site s and line n for lower level problem

$\Theta_{t,s}^{i,n}$ Production time variable for upper level problem

$ts_{t,s}^{n,\ell}$ Start time of slot ℓ

$te_{t,s}^{n,\ell}$ End time of slot ℓ

$sh_{t,s}^{i,m}$ Shipment of product i from manufacturing site s to market m at time period t

$sh_{t,s}^{i,m}$ Shipment variable for upper level problem

$z_{t,s}^{i,k,n,\ell}$ Continuous variable bounded at 0 and 1 to denote a transition between products i and k

$trt_{t,s}^{i,k,n}$ Binary variable denoting changeovers across between products i and k across adjacent periods

$ny_{t,s}^{i,n}$ Number of slots of product i in time t

$w_{t,s}^{i,n,\ell}$ Binary variable to denote if product i is produced in slot ℓ of line n at site s in period t

$yp_{t,s}^{i,n}$ Binary variable in upper level problem to denote if product i is produced in line n at site s in period t

$yop_{t,s}^{i,n}$ Binary variable for limiting search the space of $w_{t,s}^{i,n,\ell}$ in lower level problem

$x_{t,s}^{i,n}$	Binary variable to denote if product i is the first product manufactured in site s during period t
$x_{t,s}^{l,i,n}$	Binary variable to denote if product i is the last product manufactured in site s during period t
$z_{t,s}^{i,k,n}$	Binary variable to denote if product i precedes product k in unit m during time period t
$zz_{t,s}^{i,k,n}$	Binary variable that indicates if the link between products i and k is broken
$zzz_{t,s}^{i,k,n}$	Binary variable denoting changeovers across between products i and k across adjacent periods

Integrated planning and scheduling model

Equation (1) represents the objective function of the integrated problem. The first term corresponds to the product sales minus the shipment costs; we assume that all products shipped to a market are sold. The second term are the production and inventory costs, and the third term represents the cost of transitions.

$$\begin{aligned} \max \pi = & \sum_{t \in T} \left[\sum_{i \in I} \sum_{m \in M} \sum_{s \in S} (\beta_{t,s}^{i,m} - \gamma_{t,s}^{i,m}) sh_{t,s}^{i,m} - \sum_{i \in I} \sum_{s \in S} (\alpha_{t,s}^i p_{t,s}^i + \delta_{t,s}^i v_{t,s}^i) \right] \\ & - \sum_{i \in I} \sum_{k \in K} \sum_{n \in N} \sum_{t \in T} \sum_{s \in S} TC_{t,s}^{i,k} \left(\sum_{\ell \in L} z_{t,s}^{i,k,\ell,n} + trt_{t,s}^{i,k,n} \right) \end{aligned} \quad (1)$$

In equation (2) the sum of the production at each slot is aggregated into the variable p that stands for the total production of product i in site s during period t .

$$\sum_{n \in N} \sum_{\ell \in L} x_{t,s}^{i,n,\ell} = p_{t,s}^i \quad i \in I, s \in S, t \in T \quad (2)$$

The set of equations in (3) represents the mass balances for every product at the end of each time period in every site.

$$v_{t-1,s}^i + p_{t,s}^i = \sum_{m \in M} sh_{t,s}^{i,m} + v_{t,s}^i \quad i \in I, s \in S, t \in T \quad (3)$$

Equation (4) constraints the shipments (sales) to be less than or equal to the demand at each market

$$m d_s^i \leq \sum_{s \in S} sh_{t,s}^{i,m} \leq d_t^{i,m} \quad i \in I, m \in M, t \in T \quad (4)$$

The summation in equation (5) limits the production in each slot to one product.

$$\sum_{i \in I} w_{t,s}^{i,n,\ell} = 1 \quad n \in N, \ell \in L_n, t \in T, s \in S \quad (5)$$

According to constraint (6) the production time of i in slot l can only be nonzero if it has been assigned to it.

$$\theta_{t,s}^{i,n,\ell} \leq H_t w_{t,s}^{i,n,\ell} \quad n \in N, i \in I_n, \ell \in L_n, t \in T, s \in S \quad (6)$$

Equation (7) sets the production of i to the product of the production rate times the production time.

$$x_{t,s}^{i,n,\ell} = a_s^{i,n} \theta_{t,s}^{i,n,\ell} \quad n \in N, i \in I_n, \ell \in L_n, t \in T, s \in S \quad (7)$$

In equation (8) the end time of a slot is computed as the starting time plus the production and the transition times.

$$te_{t,s}^{n,\ell} = ts_{t,s}^{n,\ell} + \sum_{i \in I_n} \theta_{t,s}^{i,n,\ell} + \sum_{i \in I_n} \sum_{k \in I_n} \sum_{\ell \in L} bt_{t,s}^{i,k,n} z_{t,s}^{i,k,n,\ell} \quad n \in N, \ell \in L_n, t \in T, s \in S \quad (8)$$

Constraint (9) determines the starting time of the first slot of each time period.

$$ts_{t,s}^{n,\ell+1} \geq te_{t,s}^{n,|L_n|} + \sum_{i \in I_n} \sum_{k \in I_n} bt_{t,s}^{i,k,n} trt_{t,s}^{i,k,n} \quad n \in N, \ell \in L_n, t \in T, s \in S \quad (9)$$

By equation (10), the ending time of a slot is equal to the starting time of the one immediately following it.

$$ts_{t,s}^{n,\ell+1} = te_{t,s}^{n,\ell} \quad n \in N, i \in I_n, \ell \in L_n, \ell < |L_n|, t \in T, s \in S \quad (10)$$

Constraint (11) ensures that no time slot ends after the end of the time period t to which it belongs.

$$te_{t,s}^{n,|L_n|} + \sum_{i \in I_n} \sum_{k \in I_n} bt_{t,s}^{i,k,n} trt_{t,s}^{i,k,n} \leq H_t \quad n \in N, \ell \in L_n, t \in T, s \in S \quad (11)$$

Equations (12) and (13) assign the value of one to the relevant transition variable between products i and k produced in adjacent slots in the same time period.

$$\sum_{k \in I_n} z_{t,s}^{i,k,n,\ell} = w_{t,s}^{i,n,\ell} \quad n \in N, i \in I_n, \ell \in L_n, t \in T, s \in S \quad (12)$$

$$\sum_{i \in I_n} z_{t,s}^{i,k,n,\ell} = w_{t,s}^{i,n,\ell+1} \quad n \in N, i \in I_n, \ell \in L_n, t \in T, s \in S \quad (13)$$

Equations (14) and (15) assign the value of one to the relevant transition variable between products i and k produced in adjacent slots in the across time period.

$$\sum_{k \in I_n} trt_{t,s}^{i,k,n} = w_{t,s}^{i,n,|L_n|} \quad n \in N, i \in I_n, t \in T, s \in S \quad (14)$$

$$\sum_{i \in I_n} trt_{t,s}^{i,k,n} = w_{t+1,s}^{i,n,1} \quad n \in N, i \in I_n, t \in T, s \in S \quad (15)$$

The same product can be assigned to several adjacent slots if the total number of slots is greater than the number of products assigned for production during a time period. The extra slots in this situation are labeled “flexible slots”. Since the duration of time slots is variable, this can result in degenerate assignment of products. The set of constraints (16) – (19) prevents such degeneracy by enforcing that all flexible slots be assigned to the first product in the production sequence. Erdirik-Dogan and Grossmann (2006) provide a detailed explanation of these constraints.

$$yop_{t,s}^{i,n} \geq w_{t,s}^{i,n,\ell} \quad n \in N, i \in I_n, \ell \in L_n, t \in T, s \in S \quad (16)$$

$$yop_{t,s}^{i,n} \leq ny_{t,s}^{i,n} \quad n \in N, i \in I_n, t \in T, s \in S \quad (17)$$

$$ny_{t,s}^{i,n} \leq |L_n| yop_{t,s}^{i,n} \quad n \in N, i \in I_n, t \in T, s \in S \quad (18)$$

$$ny_{t,s}^{i,n} \geq |L_n| - \sum_{k \in I_n} yop_{t,s}^{i,n} - 1 - bigM(1 - w_{t,s}^{i,n,\ell}) \quad n \in N, i \in I_n, \ell \in L_n, t \in T, s \in S \quad (19)$$

$$ny_{t,s}^{i,n} \leq |L_n| - \sum_{k \in I_n} yop_{t,s}^{i,n} - 1 + bigM(1 - w_{t,s}^{i,n,\ell}) \quad n \in N, i \in I_n, \ell \in L_n, t \in T, s \in S \quad (20)$$

Constraints (21) and (22) enforce maximum capacity for storage and transportation

$$v_{t,s}^i \leq v_{s,i}^{UB} \quad i \in I, s \in S, t \in T \quad (21)$$

$$sh_{t,s}^{i,m} \leq sh_{s,m,i}^{UB} \quad i \in I, m \in M, s \in S, t \in T \quad (22)$$

Model (PS) given by equations (1) – (22) defines the optimal multi-site multi-market integrated planning and problem.

Solution Method

The formulation (PS) involves detailed scheduling of several manufacturing sites of continuous multiproduct plants over a planning horizon that can cover weeks or months. Short-term scheduling for a single site is a challenging problem that when integrated with medium of long term planning of a process network can become computationally intractable. In fact most production scheduling problems such as the one considered in this paper are NP-hard (Garey & Johnson, 1979). Even though recent developments in computational capabilities allow the solution of larger optimization problems, decomposition algorithms provide a practical

approach for solving industrial scheduling problems. Therefore, our goal in this work is to develop an optimization approach to solve realistic problem instances of (PS) in a reasonable amount of time, meaning in no more than a couple of hours. In this section we describe an algorithm based on bi-level and Lagrangean decompositions to solve instances of (PS) considerable faster than in full-space. We first describe the bi-level decomposition of (PS), followed by the hybrid bi-level Lagrangean decomposition.

Bi-level decomposition

We extend the bi-level decomposition strategy for planning and scheduling as proposed by Erdirik-Dogan and Grossmann (2008) to the multi-site multi-market case. The main idea is to only address the temporal part of the problem decomposing the planning and scheduling parts of the problem in such a way that the planning problem over all sites and markets contains some of the information required to obtain a feasible solution at the scheduling level and that iterative solution of both problems converge to the optimal solution of (PS). This is achieved by: (i) using an aggregate sequencing model at the planning level to account for sequence-dependent transitions using traveling salesman problem (TSP) constraints; (ii) limiting the search space of the binary variables at the scheduling level using the solution of the planning problem; (iii) adding integer cuts to the planning problem to provide a tighter representation of the scheduling problem, which we should note is optimized simultaneously over all production sites and markets. The planning problem with aggregate sequencing considerations is called the upper-level planning problem (UP) and is given by the following model:

Upper-level planning problem

$$\begin{aligned} \max \pi p = & \sum_{t \in T} \sum_{s \in S} \sum_{m \in M} \sum_{i \in I} \beta_{t,s}^{i,m} s h t_{t,s}^{i,m} - \sum_{t \in T} \sum_{s \in S} \sum_{i \in I} (\alpha_{t,s}^i p_{t,s}^i + \delta_{t,s}^i v t_{t,s}^i) \\ & - \sum_{t \in T} \sum_{s \in S} \sum_{m \in M} \sum_{i \in I} \gamma_{t,s}^{i,m} s h t_{t,s}^{i,m} - \sum_{t \in T} \sum_{s \in S} \sum_{i \in I} \sum_{k \in K} \sum_{n \in N} T C_{t,s}^{i,k,n} (z p_{t,s}^{i,k,n} + z z z_{t,s}^{i,k,n} - z z p_{t,s}^{i,k,n}) \end{aligned} \quad (23)$$

s. t.

$$\sum_{n \in N} x t_{t,s}^{i,n} = p t_{t,s}^{i,n} \quad i \in I, s \in S, t \in T \quad (24)$$

$$v_{t-1,s}^i + pt_{t,s}^i = \sum_{m \in M} sht_{t,s}^{i,m} + v_{t,s}^i \quad i \in I, s \in S, t \in T \quad (25)$$

$$m ds_m^i \leq \sum_{s \in S} sht_{t,s}^{i,m} \leq d_t^{i,m} \quad i \in I, m \in M, t \in T \quad (26)$$

$$\theta_{t,s}^{i,n} \leq L_t y p_{t,s}^{i,n} \quad n \in N, i \in I_n, t \in T, s \in S \quad (27)$$

$$x t_{t,s}^{i,n} = a_s^{i,n} \theta_{t,s}^{i,n} \quad n \in N, i \in I_n, t \in T, s \in S \quad (28)$$

$$\sum_{i \in I_n} \left(a_{t,s}^{i,n} x_t^{s,i} + \sum_{k \in I_n} b t_{t,s}^{i,k,n} (z p_{t,s}^{i,k,n} + z z z_{t,s}^{i,k,n} - z z p_{t,s}^{i,k,n}) \right) \leq L_t \quad n \in N, s \in S, t \in T \quad (29)$$

$$y p_{s,t}^{i,m} = \sum_{k \in I_n} z p_{s,t}^{i,k,m} \quad n \in N, i \in I_n, s \in S, t \in T \quad (29)$$

$$y p_{s,t}^{k,m} = \sum_{i \in I_n} z p_{s,t}^{i,k,n} \quad n \in N, k \in I_n, s \in S, t \in T \quad (30)$$

$$\sum_{i \in I_n} \sum_{k \in K_n} z z p_{t,s}^{i,k,n} = 1 \quad n \in N, s \in S, t \in T \quad (31)$$

$$z z p_{t,s}^{i,k,n} \leq z p_{t,s}^{i,k,n} \quad n \in N, i \in I_n, k \in I_n, s \in S, t \in T \quad (32)$$

$$y p_{t,s}^{i,n} \geq z p_{t,s}^{i,i,n} \quad n \in N, i \in I_n, s \in S, t \in T \quad (33)$$

$$z p_{t,s}^{i,i,n} + y p_{t,s}^{k,n} \leq 1 \quad n \in N, i \in I, k \in I, i \neq k, s \in S, t \in T \quad (34)$$

$$z p_{t,s}^{i,i,n} \geq y p_{t,s}^{i,n} - \sum_{k \neq i, k \in I} y p_{t,s}^{k,n} \quad n \in N, i \in I_n, s \in S, t \in T \quad (35)$$

$$x f_{t,s}^{k,n} \geq \sum_{i \in I_n} z z p_{t,s}^{i,k,n} \quad n \in N, k \in I_n, s \in S, t \in T \quad (36)$$

$$x l_{t,s}^{i,n} \geq \sum_{k \in I_n} z z p_{t,s}^{i,k,n} \quad n \in N, i \in I_n, s \in S, t \in T \quad (37)$$

$$\sum_{i \in I_n} x f_{t,s}^{i,n} = 1 \quad n \in N, i \in I_n, s \in S, t \in T \quad (38)$$

$$\sum_{i \in I_n} x l_{t,s}^{i,n} = 1 \quad n \in N, i \in I_n, s \in S, t \in T \quad (38)$$

$$\sum_{k \in I_n} z z z_{t,s}^{i,k,n} = x l_{t,s}^{i,n} \quad n \in N, i \in I_n, s \in S, t \in T \quad (40)$$

$$\sum_{i \in I_n} z z z_{s,t}^{i,k,n} = x f_{t+1,s}^{k,n} \quad n \in N, k \in I_n, s \in S, t \in T \quad (41)$$

$$v_{t,s}^i \leq v_{s,i}^{UB} \quad i \in I, s \in S, t \in T \quad (42)$$

$$sht_{t,s}^{i,m} \leq sht_{s,m,i}^{UB} \quad i \in I, s \in S, m \in M, t \in T \quad (43)$$

$$\sum_{(i,n,t,s) \in Z_1^r} y p_{t,s}^{i,n} \leq |Z_1^r| - 1 \quad r \in R_{cut} \quad (44)$$

Equation (44) is called an integer cut, and it is used to exclude combinations of assignment variables that are proven to result in a worse solution to the problem (UP) than that found at iteration r . These integer cuts are explained in more detail by Eridirik-Dogan and Grossmann (2008). Here $Z_1^r = \{i, n, t, s : yp_{t,s}^{i,n,r} = 1\}$, and $R_{cut} = \{r : r \text{ is a bi-level iteration used to construct an integer cut}\}$

Lower-level scheduling problem

The lower level subproblem (PL) corresponds to equations (1) – (22) plus constraint (45) given below, which restricts the products i that are to be produced at each line n of site s at time period t to those in the optimal solution of the upper level problem ($\hat{yp}_{t,s}^{i,n}$ is the optimal assignment in the planning problem (UP)). This last equation has the effect of limiting the search space of the binary assignment values and speeds up the solution of (PL).

$$yop_{t,s}^{i,n} \leq \hat{yp}_{t,s}^{i,n} \quad i \in I, s \in S, m \in M, t \in T \quad (45)$$

Hybrid bi-level Lagrangean decomposition

This section describes the proposed algorithm for solving large-scale instances of problem (PS) by addressing both the temporal and spatial parts of the problem. It builds on the methodology of bi-level decomposition by using Lagrangean decomposition to solve the upper-level problem for *individual sites*. The idea of the hybrid algorithm is to add a new shipping variable $\hat{sht}_{t,s}^{i,m}$ and constraint $sht_{t,s}^{i,m} = \hat{sht}_{t,s}^{i,m}$ to the upper-level problem defined by equations (23) – (44). The variable $sht_{t,s}^{i,m}$ is substituted for $\hat{sht}_{t,s}^{i,m}$ in equation (26), yielding:

$$mds_m^i \leq \sum_{s \in S} \hat{sht}_{t,s}^{i,m} \leq d_t^{i,m} \quad i \in I, m \in M, t \in T \quad (46)$$

The constraint $sh_{t,s}^{i,m} = \hat{sh}_{t,s}^{i,m}$ is dualized using Lagrangean relaxation (Geoffrion, 1974), which has the effect of spatially decomposing the problem as shown in Figure 2. In this way the objective function (23) becomes:

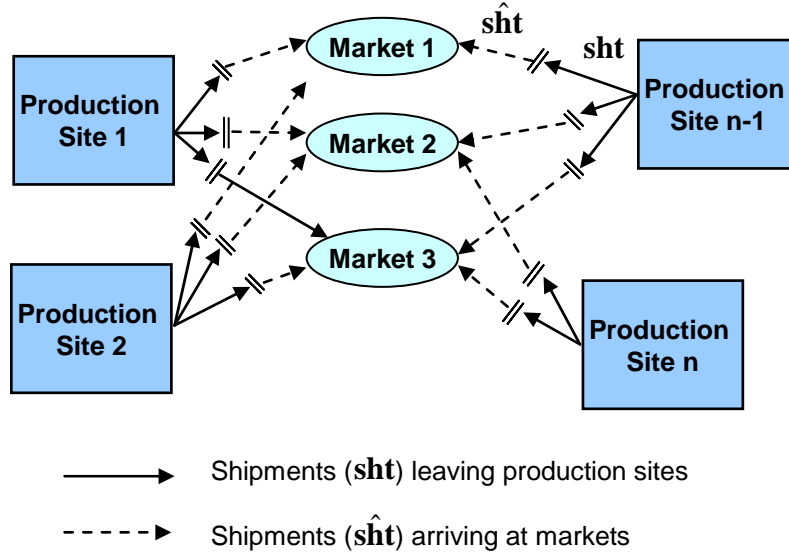

Figure 2. Schematic representation of the relaxation of constraint $sh_{t,s}^{i,m} = \hat{sh}_{t,s}^{i,m}$

$$\begin{aligned}
 \max \pi pl(\lambda) = & \sum_{t \in T} \sum_{s \in S} \sum_{m \in M} \sum_{i \in I} \beta_{t,s}^{i,m} \hat{sh}_{t,s}^{i,m} - \sum_{t \in T} \sum_{s \in S} \sum_{i \in I} (\alpha_{t,s}^i p_{t,s}^i + \delta_{t,s}^i v_{t,s}^i) \\
 & - \sum_{t \in T} \sum_{s \in S} \sum_{m \in M} \sum_{i \in I} \gamma_{t,s}^{i,m} \hat{sh}_{t,s}^{i,m} - \sum_{t \in T} \sum_{s \in S} \sum_{i \in I} \sum_{k \in K} \sum_{n \in N} TC_{t,s}^{i,k,n} (z p_{t,s}^{i,k,n} + z z z_{t,s}^{i,k,n} - z z p_{t,s}^{i,k,n}) \\
 & + \sum_{t \in T} \sum_{s \in S} \sum_{m \in M} \sum_{i \in I} \lambda_{t,s}^{i,m} (sh_{t,s}^{i,m} - \hat{sh}_{t,s}^{i,m}) \tag{47}
 \end{aligned}$$

The parameter $\lambda_{t,s}^{i,m}$ is the Lagrange multiplier of the dualized constraint. We call the modified upper level problem as Upper-level Lagrangean Problem (UPL). It is defined by equations (24), (25), (27)-(45), (46), (47), and it is decomposable into subproblems for individual sites (UPL_s) $s \in S$ and individual markets (UPL_m) $m \in M$ as shown in Figure 2. The subproblem for an individual site s^* is as follows:

$$\begin{aligned}
 \max \pi pl_{s^*}(\lambda) = & \sum_{t \in T} \sum_{i \in I} (\alpha_{t,s^*}^i p_{t,s^*}^i + \delta_{t,s^*}^i v_{t,s^*}^i) - \sum_{t \in T} \sum_{m \in M} \sum_{i \in I} \gamma_{t,s^*}^{i,m} \hat{sh}_{t,s^*}^{i,m} \\
 & - \sum_{t \in T} \sum_{i \in I} \sum_{k \in K} \sum_{n \in N} TC_{t,s^*}^{i,k,n} (z p_{t,s^*}^{i,k,n} + z z z_{t,s^*}^{i,k,n} - z z p_{t,s^*}^{i,k,n}) + \sum_{t \in T} \sum_{m \in M} \sum_{i \in I} \lambda_{t,s^*}^{i,m} sh_{t,s^*}^{i,m}
 \end{aligned}$$

s.t.

Equations (24), (25), (27) – (44) specified for $s = s^*$ (UPL_{s*})

while the subproblem for market m^* corresponds to:

$$\max \pi pl_m(\lambda) = \sum_{t \in T} \sum_{s \in S} \sum_{i \in I} \beta_{t,s}^{i,m^*} \hat{s}ht_{t,s}^{i,m^*} - \sum_{t \in T} \sum_{s \in S} \sum_{i \in I} \lambda_{i,s}^{i,m^*} (\hat{s}ht_{t,s}^{i,m^*})$$

s.t.

$$m ds_m^i \leq \sum_{s \in S} \hat{s}ht_{t,s}^{i,m^*} \leq d_t^{i,m^*} \quad \forall i \in I, t \in T \text{ and } \hat{s}ht_{t,s}^{i,m^*} \leq sht_{s,m,i}^{UB} \quad \forall s \in S, i \in I, t \in T \text{ (UPL}_{m^*})$$

It can be verified that the optimal objective value in (UPL) is equal to the sum of optimal values of (UPL_s) $s \in S$ and (UPL_m) $m \in M$. That is,

$$\max \pi pl(\lambda) = \sum_{s \in S} \max \pi pl_s(\lambda) + \sum_{m \in M} \max \pi pl_m(\lambda).$$

Figure 3 contains the flow diagrams of bi-level and hybrid algorithms (bi-level + Lagrangean decomposition).

$\hat{y}_{t,s}^{i,n}$ denotes product assignments to lines, sites, and time periods in the solution to the UPPERLEVEL

$yop_{i,s}^{i,n}$ binary to denote production of product i in line n of site s during period t in LOWERLEVEL

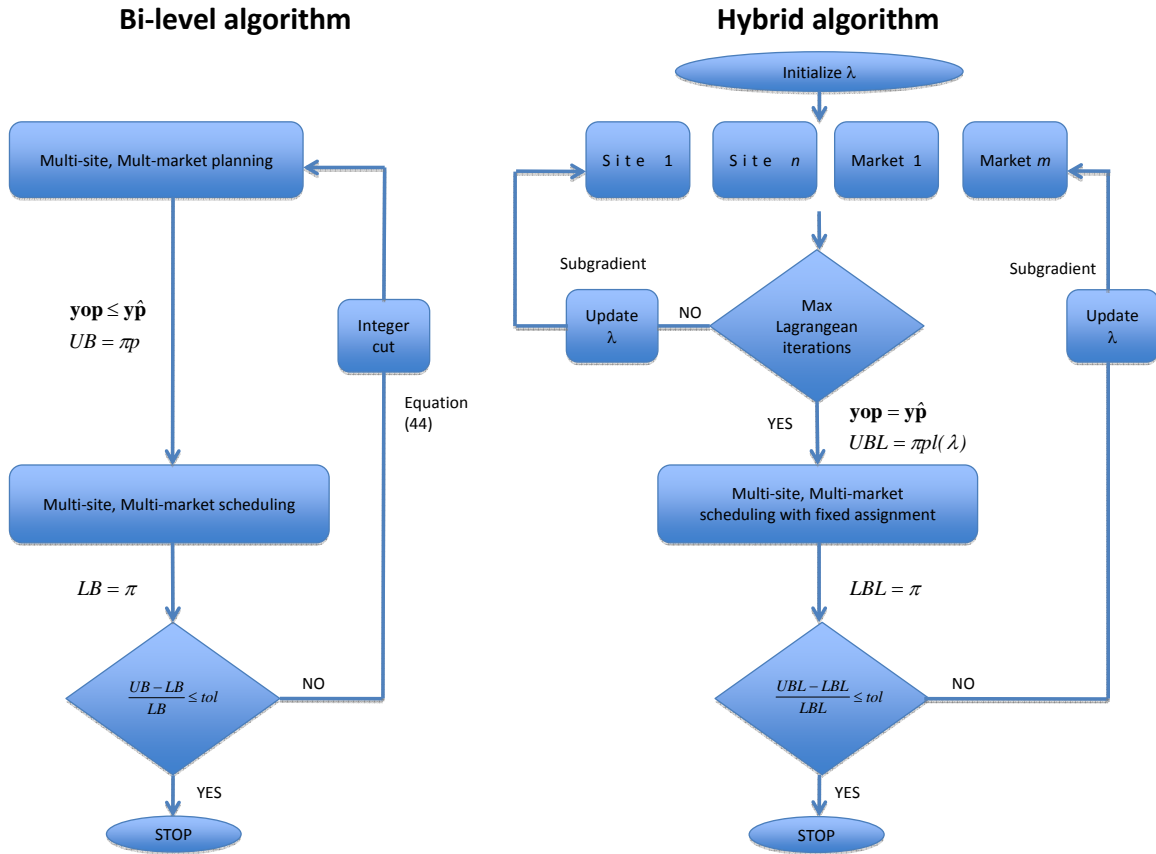

Figure 3. Comparison of bi-level and hybrid algorithms

Remarks

1. Computational results in Erdirik-Dogan and Grossmann (2008) show that the upper-level problem – (UP) in this paper – is the bottleneck in the bi-level decomposition algorithm. Speeding up the solution of (UP) could speed up the convergence of the bi-level method. For a given $\lambda_{t,s}^{i,m}$, upper-level Lagrangean problem (UPL) can be solved for each manufacturing site and each market at a time, decreasing the computation time of (UP).
2. The value of $\pi pl(\lambda)$ in (UPL) for any λ is guaranteed to yield an upper bound for πp in (UP) (Guigand and Kim, 1987). We also know that πp in (UP) is an upper bound to π in (PS). Since $\pi pl(\lambda) \geq \pi p \geq \pi$ for any λ , (UPL) is always an upper bound to (PS).
3. Terrazas-Moreno et al. (2010) show that the optimal Lagrange multiplier of the relaxed constraint $sh_{t,s}^{i,m} = \hat{sh}_{t,s}^{i,m}$ can be approximated by the transfer price of product i between site s and market m . A value close to this transfer price can be obtained by adding to problem (UPL) $sh_{t,s}^{i,m} = \hat{sh}_{t,s}^{i,m}$, solving a linear relaxation of the augmented problem, and reading the optimal dual variable of $sh_{t,s}^{i,m} = \hat{sh}_{t,s}^{i,m}$.
4. The solution to the optimization problem $\min_{\lambda} \pi pl(\lambda)$ yields the tightest upper bound to (UP). The value of λ initialized as described in the previous remark, can be improved using subgradient method (Held et al., 1974) to bring closer to the optimal multiplier λ^* , where $\pi pl(\lambda^*) = \min_{\lambda} \pi pl(\lambda)$.
5. The solution πs of lower-level problem (PL) with assignment variables fixed to those obtained in the solution of the upper-level problem ($yop_{t,s}^{i,n} = \hat{y}p_{t,s}^{i,n}$) provides a heuristic lower bound that is valid on π in the original planning and scheduling problem (PS). Considering remark 2, $\pi s \leq \pi \leq \pi p \leq \pi pl$. The hybrid algorithm described in this paper uses πs as a lower bound and πpl as an upper bound to (PS), and provides an iterative procedure that can minimize the magnitude of $\pi pl - \pi s$.

Algorithmic steps

The description that follows of the hybrid algorithm complements the graphic representation of it in Figure 3.

Step 1

Initialize algorithm parameters:

B^{it} Maximum number of bi - level iterations

L^{it} Maximum number of Lagrangean iteration at each bi - level iteration

UB^1 Initial upper bound

LB^1 Initial lower bound

$r = 1, \dots, B^{it}$ bi - level iteration index

$q = 1, \dots, L^{it}$ Lagrangean iteration index

$m ds_m^i$ minimum required percentage of demand satisfaction

Step 2

Solve the linear relaxation of the following problem:

$$\begin{aligned}
 \max \pi pl(\lambda) = & \sum_{t \in T} \sum_{s \in S} \sum_{m \in M} \sum_{i \in I} \beta_{t,s}^{i,m} \hat{s}ht_{t,s}^{i,m} - \sum_{t \in T} \sum_{s \in S} \sum_{i \in I} (\alpha_{t,s}^i p_{t,s}^i + \delta_{t,s}^i v_{t,s}^i) \\
 & - \sum_{t \in T} \sum_{s \in S} \sum_{m \in M} \sum_{i \in I} \gamma_{t,s}^{i,m} \hat{s}ht_{t,s}^{i,m} - \sum_{t \in T} \sum_{s \in S} \sum_{i \in I} \sum_{k \in K} \sum_{n \in N} TC_{t,s}^{i,k,n} (z_{t,s}^{i,k,n} + z z z_{t,s}^{i,k,n} - z z p_{t,s}^{i,k,n}) \\
 & + \sum_{t \in T} \sum_{s \in S} \sum_{m \in M} \sum_{i \in I} \lambda_{t,s}^{i,m} (sht_{t,s}^{i,m} - \hat{s}ht_{t,s}^{i,m})
 \end{aligned}
 \tag{UPLa}$$

s.t

$$\text{Equations(24),(25),(27) - (44),(46), } sht_{t,s}^{i,m} = \hat{s}ht_{t,s}^{i,m} \quad \forall i \in I, m \in M, t \in T, s \in S$$

Step 3

Assign the value of the optimal dual multiplier of constraint $sht_{t,s}^{i,m} = \hat{s}ht_{t,s}^{i,m}$ to $\lambda_{t,s}^{i,m}$ for iteration $q = 1, r = 1$.

Step 4

For $r = 1, \dots, B^{it}$,

For $q = 1, \dots, L^{it}$,

With $\lambda_{t,s}^{i,m,q,r}$ solve the site subproblems (UPL_s)

$\forall s \in S$ and market subproblems (UPL_m) $\forall m \in M$ and compute the upper bound as:

$$\pi pl(\lambda^{q,r}) = \sum_{s \in S} \pi pl_s(\lambda^{q,r}) + \sum_{m \in M} \pi pl_m(\lambda^{q,r}).$$

If $\pi pl(\lambda^{q,r}) \leq UB^r$,

$$UB^{r+1} = \pi pl(\lambda^{q,r}),$$

$$y\hat{p}_{t,s}^{i,n,r} = yp_{t,s}^{i,n},$$

end if

$$\lambda_{t,s}^{i,m,q+1,r} = \lambda_{t,s}^{i,m,q,r} + \varepsilon \frac{(UB^{q,r} - LB^{q,r})}{\sum_{t \in T} \sum_{s \in S} \sum_{m \in M} \sum_{i \in I} (sh_{t,s}^{i,m} - \hat{sh}_{t,s}^{i,m})^2} \cdot (sh_{t,s}^{i,m} - \hat{sh}_{t,s}^{i,m})$$

end For

$q = 1$

$$\lambda_{t,s}^{i,m,q,r+1} = \lambda_{t,s}^{i,m,L^i,r}$$

Solve (PL) with fixed product assignment ($yp_{t,s}^{i,n} = y\hat{p}_{t,s}^{i,n,r}$)

If $\pi \geq LB^r$

$$LB^{r+1} = \pi$$

end if

If $\frac{UB^{r+1} - LB^{r+1}}{|LB^{r+1}|} \leq tol$

STOP

Else

$$r = r + 1$$

End if

End For

Remark: We keep the set R_{cut} empty at all times to avoid generating integer cuts in equation (44). The reason is as follows. In bi-level decomposition equation (44) has the objective of avoiding the same integer solution and certain subset and superset of the solution obtained in the upper level problem at previous iterations. Since the coefficients in the objective function of the upper level problem (equation (23)) do not change, it is guaranteed that the integer cuts do not cut off better solutions (higher in maximization problems) than those found in previous iterations. When the upper level is decomposed using Lagrangean decomposition, the parameter $\lambda_{t,s}^{i,m}$ that stands for the Lagrange multiplier is updated at every iteration in the decomposable objective function (Equation (47)). Since some of the coefficients in the objective function (namely, $\lambda_{t,s}^{i,m}$) change in every iteration, it is not possible to guarantee that a better optimal solution in new iterations will not correspond to the same, or a subset or superset, of a previous integer solution. This fact destroys the properties that allow the use of equation (44) in problem (UP).

Case Studies

Example 1

A small manufacturing and distribution network consists of 3 production sites with single production lines serving 2 markets that demand products A, B, and C. The objective is to obtain the optimal planning and detailed production schedule for 4 weeks.

Table 1 shows the maximum production rates in each site, while Tables 2a and 2b contain values of market demand for all products and the minimum levels of demands that must be satisfied. Table 3 and 4 show the market price as well as the production, inventory, and distribution costs. Finally, Table 5 contains transition times and costs.

Table 1. Maximum Production Rates

Product	Site 1 [kg/hr]	Site 2 [kg/hr]	Site 3 [kg/hr]
A	1110	4860	2780
B	4170	3470	4860
C	4170	4270	1390

Table 2a. Demand for products at markets

Product	Week	Market 1 [10³kg/week]	Market 2 [10³kg/week]
A	1	175.0	187.5
	2	275.0	150.0
	3	500.0	600.0
	4	750.0	750.0
B	1	200.0	100.0
	2	150.0	312.5
	3	600.0	600.0
	4	900.0	950.0
C	1	175.0	200.0
	2	100.0	50.0
	3	700.0	700.0
	4	950.0	990.0

Table 2b. Minimum percentage of demands that must be satisfied

Product	Market 1 [%]	Market 2 [%]
A	50	50
B	50	50
C	50	50

The market demand is low during the first two weeks and high in the last two. The spare capacity in the first couple of weeks can be used to build inventories and take advantage of the later increase in demand. By requiring that a minimum of 50% of demand be satisfied, we prevent the less profitable products from being completely ignored in favor of more profitable ones. This consideration is important in industrial settings where a minimum demand satisfaction is required to remain competitive in most markets.

Table 3. Market price and production, and inventory costs

Product		Site 1 [10 ⁻³ \$/kg]	Site 2 [10 ⁻³ \$/kg]	Site 3 [10 ⁻³ \$/kg]	Market 1 [10 ⁻³ \$/kg]	Market 2 [10 ⁻³ \$/kg]
A	Price				20	23
	Production	2.5	3.5	3.5		
	Inventory	5.0	5.0	5.0		
B	Price				12	19
	Production	4.5	4.0	4.5		
	Inventory	5.0	5.0	5.0		
C	Price				16	15
	Production	3.5	2.5	4.5		
	Inventory	6.0	6.0	6.0		

Table 4. Distribution costs

Product		Site 1 [10 ⁻³ \$/kg]	Site 2 [10 ⁻³ \$/kg]	Site 3 [10 ⁻³ \$/kg]
A	Market 1	4.0	3.0	3.0
	Market 2	5.0	6.5	4.0
B	Market 1	2.0	1.0	2.0
	Market 2	5.0	6.0	5.5
C	Market 1	5.0	4.0	6.5
	Market 2	2.5	2.0	3.0

Table 5. Transition time and cost

		From / To	A	B	C
			[hr]	[hr]	[hr]
Transition time	A		0	24	12
	B		24	0	12
	C		24	24	0
		From / To	A	B	C
			[\$]	[\$]	[\$]
Transition cost*	A		0	100	200
	B		150	0	300
	C		100	250	0

* Transition costs are independent of amount of product.

Table 3 to 5 show that the production of every product is profitable. Production capacity and market demand are such that production sites can be run at, or close to, their maximum capacity, especially in the third and fourth weeks. Therefore, the optimal solution will involve the best possible utilization of production capacity to produce and sell as much as possible.

Example 1 is a small case study so it is possible to obtain an optimal solution without decomposition techniques. Its small size also makes it easy to analyze the optimal solution. We use bi-level and bi-level-Lagrangean decompositions to solve Example 1, in addition to the full space model, with the objective of comparing each of the solutions. It is worth to clarify that we do not expect the hybrid algorithm to be faster than the full space model in this example. It is almost always the case that the comparative performance of decomposition methods versus full space models improves as problem size grows.

The full space model consists of 144 discrete variables, 901 continuous variables, and 1222 constraints. We solve it using CPLEX 12.1.0 in GAMS version 23.3.3 for Windows, using an Intel Pentium 4 CPU at 2.80 GHz, and 2.50 GB of RAM. We use the same software and hardware for all the calculations in this paper. The solution time is about 4 CPU second. The following analysis corresponds to the solution obtained using the full space model.

Figure 4 is a Gantt chart that corresponds to the optimal production schedule for every site. Product A is assigned more production time since it is the most profitable. This is expected since the objective function of the problem is profit. In this small example the number of products and production sites is equal, so there is no need for many product transitions. In fact, after week 2, each site is dedicated to a single product. Figure 5 reveals that there is spare capacity in the production sites during weeks 1,2 and 3, so there is a chance to build product inventory in preparation for high demand at the end of the time horizon.

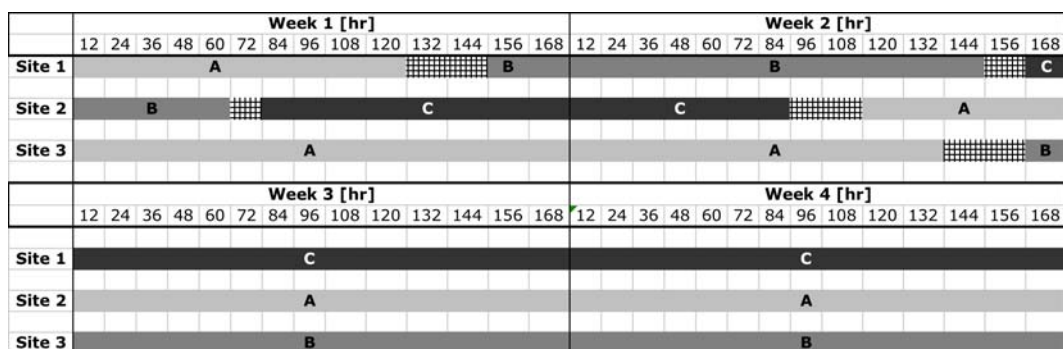

Figure 4. Optimal production schedule

Figure 5. End of week inventories

Table 6 shows the sales as a percentage of the demand in the markets (Table 2). The information in this table confirms that during weeks 1 and 2 all the demand is satisfied. During weeks 3 and 4 the demand exceeds production capacity, and even with inventories carried over from the first two weeks, it is not possible to satisfy all demand. The optimal profit calculated as revenues minus costs is shown in Table 7.

Table 6. Sales as percentage of demand

Product	Week	Market 1	Market 2
		[10 ³ kg/week]	[10 ³ kg/week]
A	1	100%	100%
	2	100%	100%
	3	100%	100%
	4	82%	50%
B	1	100%	100%
	2	100%	100%
	3	50%	100%
	4	50%	50%
C	1	100%	100%
	2	100%	100%
	3	50%	50%
	4	50%	50%

Table 7. Optimal profit for Example 1

Revenues [\$]	136,928
Operating costs [\$]	28,417
Inventory costs [\$]	9,051
Transition costs [\$]	900
Distribution costs [\$]	28,849
Profit [\$]	69,711

Next, the bi-level and bi-level-Lagrangean decompositions are used to solve Example 1. The objective is to compare the solutions obtained with these two methods. The advantage in terms of computational time, particularly of the hybrid method, will be demonstrated in Examples 2, 3 and 4.

The bi-level decomposition is implemented as described in earlier sections of this paper. The upper level problem has 324 discrete variables, 337 continuous variables, and 757 constraints. As mentioned before, the upper level (planning problem) contains an aggregated sequencing model that is able to take into account sequence dependent product transitions. On the other hand, the lower level corresponds to the full space model where the search space of the binary variables is reduced according to the solution of the upper level problem. The lower level has 144 discrete variables, 901 continuous variables, and 1258 constraints. The bi-level decomposition algorithm converges in one single iteration (upper and lower level have the same solution) and takes less than one CPU second in total. The detailed schedule, and optimal profit is the same as the full space problem.

The bi-level Lagrangean decomposition algorithm takes 10 seconds to converge within a 2% tolerance between the upper and lower level solutions. Before going into more detail with the analysis of the solution it is worth making the remark that it is expected for this algorithm to perform worse than the solution using the full space model, and even the bi-level algorithm by itself, *for small examples like Example 1*. After all, the algorithm requires several iterations to obtain a relaxed solution to the upper level problem of the bi-level algorithm. Relaxing the upper level pays off with less computational time for larger example. In this example we use a maximum of 20 bi-level iterations (although the algorithm usually converges

in fewer) and 5 Lagrangean iterations per bi-level iteration. Table 8 shows the value of the bounds for different iterations. After 3 major, bi-level iterations, the bound between the solution to the relaxed upper level problem and the solution to the lower level problem are within a 2% tolerance. The best upper and lower bounds in Table 5 are highlighted.

Remark: The duality gap between the optimal solution of the upper level problem and the solution to the Lagrangean relaxation of the upper level problem makes convergence to 0% tolerance between upper and lower level problems unlikely. The trade-off is that *in larger problems* the solution to the relaxed upper level problem can be more efficient than the direct solution.

Table 8. Value of upper and lower bounds in \$ for each iteration of the hybrid algorithm

		Lagrangean iterations for solving the upper level problem				
Bi-level iterations	Bound	1	2	3	4	5
1	Upper	71,029	71,511	71,686	71,817	71,537
	Lower	69,513				
2	Upper	71,879	71,643	71,430	71,348	71,206
	Lower	68,900				
3	Upper	71,089	71,046	70,915	70,888	-
	Lower	68,900				

Remark 3 in the Solution Method section states that by initializing the Lagrange multipliers $\lambda_{t,s}^{i,m}$, with the optimal value of the dual variable that corresponds to $sh_{t,s}^{i,m} = \hat{sh}_{t,s}^{i,m}$ in the linear relaxation of (UPL) we obtain a value close to the transfer value between site s and market m of product i in time period t . Furthermore, the same remark states that this value is close to the optimum for the corresponding Lagrange multiplier. Terrazas-Moreno et al. (2010) explain how in a similar network where the maximum sales are limited by market demand, the equilibrium transfer prices are close to the production costs $\alpha_{t,s}^i$, whereas in the case where sales are limited by production capacity, the equilibrium transfer prices are close to the product price minus the shipment cost. We illustrate this

using product A transferred between site 1 and market 1 in all time periods as an example. Table 9 contains, for the example just mentioned, the initial value for the Lagrange multipliers ($\lambda_{t,1}^{A,1}$), their best value found (corresponding to bi-level iteration 3 and Lagrangean iteration 4 in Table 8), as well as the magnitudes of the production costs ($\alpha_{1,t}^A$), and of the product price minus the average shipment cost ($\beta_t^{A,1} - \frac{\gamma_{t,1}^{A,1} - \gamma_{t,2}^{A,1}}{2}$). The first observation from Table 9 is that the initial and best values for Lagrange multipliers are practically the same, validating the choice of initialization using the dual variables of the linear relaxation. The second observation is that in the first week the Lagrange multiplier is close to the production cost, and in the last two it is close to the price minus shipment cost value. This is consistent with the beginning of the time horizon being low demand (sales are limited by demand) and the later periods being high demand (sales limited by production capacity). The differences between the multipliers and the transfer prices calculated as $\alpha_{1,t}^A$ or $\beta_t^{A,1} - \frac{\gamma_{t,1}^{A,1} - \gamma_{t,2}^{A,1}}{2}$ can be attributed to the effect of transition cost (which must be added to the production cost) and inventory costs. The effect of inventory cost is more important in period 2, which corresponds to a low demand week, but where the Lagrange multipliers are more than twice the production costs.

Table 9. Lagrange multiplier values, production cost and product price minus shipments costs for product A

	t =1	t =2	t =3	t =4
Initial $\lambda_{t,1}^{A,1}$	0.003	0.008	0.013	0.019
Best $\lambda_{t,1}^{A,1}$	0.004	0.008	0.013	0.019
$\alpha_{1,t}^{A,1}$	0.0025	0.0025	0.0025	0.0025
$\beta_t^{A,1} - \frac{\gamma_{t,1}^{A,1} - \gamma_{t,2}^{A,1}}{2}$	0.0165	0.0165	0.0165	0.0165

Figure 6 shows the detailed scheduling obtained by using the hybrid algorithm; it corresponds to the best lower bound of \$69,513. Although the schedule is not

exactly the same as that in Figure 4, it follows the same pattern: the first couple of weeks there are a number of transitions until in the last two weeks each site is dedicated to the production of one product. Also, manufacturing of product A is favored since it is the most profitable. Comparing Figures 5 and 7 confirms that the solution obtained with the hybrid algorithm follows the same pattern of inventory building during the first weeks. The main difference is that site 1 is idle during a fraction of the first week in the schedule obtained by the hybrid algorithm. It is worth clarifying that in this work we do not consider start-up time required a plant. Overall, the bi-level-Lagrangian algorithm obtained a close to optimal solution that could be useful if the true optimal solution is not available within reasonable computational time. In this example the full space model and the bi-level decomposition performed better. However, in the following examples we will see that finding close to optimal solutions with the hybrid algorithm has computational advantages over the full space or bi-level method.

Figure 7. End of week inventories obtained with hybrid bi-level-Lagrangian algorithm

Examples 2, 3 and 4

The objective of these examples is to compare the computational performances of the full space model, bi-level decomposition, and bi-level Lagrangean algorithm in three large planning and scheduling problem instances as shown in Table 10.

Table 10. Number of production sites, markets, products, and weeks in Examples 2, 3, and 4

Example	Production sites	Markets	Products	Weeks
2	3	2	3	4
3	6	6	16	24
4	6	6	25	12

Table 11 contains the number of variables and constraints in the three examples. Data for solving these examples is available by request from the authors.

Table 11. Number of variables and constraints in full space models of Examples 2, 3, and 4

	Discrete variables	Continuous variables	Constraints
Example 2	3,264	59,713	26,390
Example 3	39,168	725,761	318,235
Example 4	46,800	1,279,799	378,139

The size of the model of Example 2 is about one order of magnitude larger than Example 1, whereas Example 3 is about one order of magnitude larger than Example 2. Example 4 corresponds to the upper limit in size of the full space model that can be handled by the hardware we are using (Intel Pentium 4 CPU at 2.80 GHz, and 2.50 GB of RAM). The idea of these differences is to analyze the effect of model size on the comparative performance of the full space model, bi-level decomposition, and bi-level-Lagrangean decomposition.

Table 12 shows that the upper level subproblem of the bi-level method has more binary variables than the full space model. This a result of the traveling salesman problem (TSP) sequencing constraints introduced into the model to capture the sequence-dependent changeovers. These sequencing constraints correspond to equations (29) – (43). In other words, the price to pay for a tight upper level

planning problem is an increase in the number of binary variables required to model sequence-dependent transitions. Precisely because of this fact, it is worth using spatial Lagrangean decomposition on the upper level (planning) problem, as is done in the hybrid bi-level-Lagrangean decomposition algorithm. Table 13 contains all the parameters that were used for the algorithm. The numerical results are summarized in Table 14.

Table 12. Size of sub problems in bi-level and bi-level-Lagrangean algorithm

	Algorithm	Subproblem	Discrete variables	Continuous variables	Constraints
Example 2	Bi-level	Upper level	6,720	4,237	8,765
		Lower level	3,264	59,713	26,582
	Hybrid	Site subproblem	2,240	1,413	2,821
		Market subproblem	-	193	129
		Lower level	3,264	59,713	26,534
Example 3	Bi-level	Upper level	80,640	60,049	106,705
		Lower level	39,168	725,761	320,539
	Hybrid	Site subproblem	13,440	10,009	17,001
		Market subproblem	-	2,305	769
		Lower level	39,168	725,761	320,443
Example 4	Bi-level	Upper level	95,400	163,073	115,561
		Lower level	46,800	1,279,799	379,939
	Hybrid	Site subproblem	15,900	10,513	18,636
		Market subproblem	-	1,801	601
		Lower level	46,800	1,279,799	379,789

Table 13. Values of the parameters used in the bi-level Lagrangean algorithm

Parameter		Example 2	Example 3	Example 4
B^{it} Max iterations	bi-level	20	20	20
L^{it} Lagrangean iterations in each bi-level iterations		2	2	2
UB^l Initial bound	upper	$+\infty$	$+\infty$	$+\infty$
LB^l Initial bound	lower	1,000	5,000	6,000
mds_m^i Min percentage of demand satisfaction		0	0	0
tol Convergence tolerance		2%	2%	2%

Table 14. Numerical results for Examples 2, 3, and 4

	Algorithm	Best solution [\$]	Solution time [CPU s]	Gap [%]	Iterations
Example 2	Full space	2,184	60	0	-
	Bi-level	2,183	9	0	1
	Hybrid	2,152	9	1.5	2
Example 3	Full space	19,886	10,000		
	Bi-level	19,859	4,939	0.1	1
	Hybrid	19,664	751	1.1	4
Example 4	Full space	-	730 [§]		
	Bi-level	10,079	7,638	0.3	1
	Hybrid	9,950	1,106	1.6	4

§ Insufficient memory after 730 CPU s

Figure 8. Solution time for case studies using full space, bi-level, and hybrid algorithms

Table 15. Percent of time spent in each sub problem for bi-level and hybrid algorithm

	Upper Level in bi-level [% CPU time]	Lower Level in bi-level [% CPU time]	Upper Level in hybrid [% CPU time]	Lower Level in hybrid [% CPU time]
Example 2	53	47	86	14
Example 3	7	93	85	15
Example 4	9	91	87	13

In the three examples we observe that the bi-level decomposition yields a solution closer to the optimum than the hybrid algorithm. This is expected since the hybrid algorithm is basically a bi-level decomposition with a relaxed upper level problem. In Example 2, both decomposition algorithms require the same computational time. However, in Examples 3 and 4 the hybrid algorithm requires considerable less time than the bi-level decomposition, and two orders or magnitude less than the full space model in Example 3. Example 4 could not be solved using the full

space model. These results are summarized in Figure 8. Table 15 shows the proportion of computational time spent solving each of the sub-problems with the two decomposition algorithms. It is interesting to see how in the bi-level decomposition most of the time in the larger examples is spent solving the lower level problem. This is in contrast with the single-site results reported by Erdirik-Dogan and Grossmann (2008). It seems that the effect of adding multiple sites and markets to the problems particularly affects the complexity of the lower level problem. More importantly, from Table 15 we can conclude that fixing the assignments obtained from the upper level in the lower level as we do for the hybrid decomposition ($y_{op} = y_p$) is an effective heuristic to obtain a feasible solution of the lower level planning and scheduling problem.

Conclusions

This paper has proposed two algorithms for solving multi-site multi-market simultaneous planning and scheduling problems involving continuous multiproduct plants. The idea is to use a bi-level decomposition, or a hybrid method where the upper level, involving the planning problem, is relaxed through Lagrangean spatial relaxation (Jackson and Grossmann, 2003). We initialize the Lagrange multiplier of the relaxed constraint using the linear relaxation. It has been observed that this value is close to the equilibrium transfer price between sites and markets, which in turn is close to the optimal Lagrange multiplier (Terrazas-Moreno et al., 2010). We show in a small example that the solution obtained with this hybrid decomposition method is similar to the one obtained with the full space planning and scheduling model. In other examples we show that the computational performance of the hybrid algorithm is similar to bi-level decomposition in medium-sized problems (Example 2) and faster in large-scale problems (Example 3 and Example 4). In all three case studies the hybrid algorithm converges within a 2% of optimality tolerance. We believe that this method is efficient for problems with tens of thousands of discrete variables, and hundreds of thousands of continuous variables and constraints. Yet, it is simple enough to be a practical alternative for obtaining tight bounds for industrial-sized planning and scheduling problems.
